

1. Q1

- a. Userspace would use `ecall` to call a trap to switch to kernel space which save all the userspace registers and handler that trap and return using `sret`. Then for kernel to return to userspace it uses `usertrapret` to restore the registers and `sret`
- b. Arguments are stored into registers before doing `ecall`, and the syscall grabs them by using literally checking which register you want and grabbing it from that threads trapframe.
